A decade ago, Faddeev and Niemi suggested that knots might exist as stable solitons in a three-dimensional classical field theory, opening up a way to investigate physical properties of knotlike structures [1]. They further proposed [2] that their model can be interpreted as the low-energy limit of the Yang-Mills theory, where knots are suggested as a natural candidate for describing glueballs—massive particles made of gluons.

In cosmology, topological defects are considered to be important for understanding the large-scale structure of our Universe [3]. Although recent measurements of the cosmic microwave background (CMB) have shown that topological defects are not the dominant source of CMB anisotropies, the search for topological objects in the Universe, such as cosmic strings, continues to be actively conducted. Recently, it has been suggested that a cosmic texture, such as cosmic strings, continues to be actively conducted. We consider a BEC of spin-1 atoms with mass $3\text{He}$ that their model can be interpreted as the low-energy limit of the Yang-Mills theory, where knots are suggested as a natural candidate for describing glueballs—massive particles made of gluons.

topology groups in spaces higher than one dimension, we have \(\pi_3(M) = \pi_3(S^2) = \mathbb{Z}\). The associated integer topological charge \(Q\) is known as the Hopf charge which is given by

\[
Q = \frac{1}{4\pi^2} \int d^3x \epsilon_{ijk} \mathbf{F}_{ij} \mathbf{n}_k,
\]

where \(\mathbf{F}_{ij} = \partial_i \mathbf{A}_j - \partial_j \mathbf{A}_i = \mathbf{n} \cdot (\partial_i \mathbf{n} \times \partial_j \mathbf{n})\) [1]. Note that the domain \((x)\) is three-dimensional, while the target space \((\mathbf{n})\) is two-dimensional. Consequently, the preimage of a point on the target \(S^2\) constitutes a closed loop in \(S^2\), and the Hopf charge is interpreted as the linking number of these loops: If the \(\mathbf{n}\) field has Hopf charge \(Q\), two loops corresponding to the preimages of any two distinct points on the target \(S^2\) will be linked \(Q\) times.

Figure 1(a) illustrates the \(\mathbf{n}\) field of a knot created in a uniform BEC with the linking number of 1. Here, the \(\mathbf{n}\) field is expressed as \(\mathbf{n}(x) = \exp[-i\alpha(r) \mathbf{v}(\theta, \phi) \cdot \hat{F}] \mathbf{n}_\infty\), subject to the boundary condition \(\mathbf{n}_\infty = (0, 0, 1)^T\) at spatial infinity, where \(x = (r \sin \theta \cos \phi, r \sin \theta \sin \phi, r \cos \theta)\) and \(\hat{F}\) is a vector of spin-1 matrices in the Cartesian representation, i.e., \(\hat{F}_j = -i \epsilon_{ijk} (j, k, l = x, y, z)\). A given mapping \(\mathbf{v}(\theta, \phi) : S^2 \rightarrow S^2\) determines the charge \(Q\), and we choose \(\mathbf{v} = (\sin \theta \cos \phi, -\sin \theta \sin \phi, \cos \theta)\) in Fig. 1(a). The radial profile function \(\alpha(r)\) is a monotonically decreasing function of \(r\), subject to the boundary conditions \(\alpha(0) = 2\pi\) and \(\alpha(\infty) = 0\). Here, we take \(\alpha(r) = 2\pi [1 - \tanh (r/\xi_{\text{knot}})]\), where \(\xi_{\text{knot}}\) is a characteristic size of the knot. Although there is no singularity in the texture, it is impossible to wind it off to a uniform configuration in a continuous manner because this texture has a nonzero Hopf charge of 1. The left part of Fig. 1(b) describes the order parameter for the \(m = -1\) component in real space, where we plot the isopycnic surface of the density and the color on the surface represents the phase. Here, \(\mathbf{n}\) on the torus is almost perpendicular to \(\mathbf{n}_\infty\) and the phase of \(\psi_{-1}\) is given by \(\arg(\psi_{-1}) = \arctan(n_y/n_x)\). The core of the knot \((\mathbf{n} = -\mathbf{n}_\infty)\) is depicted as a white tube in Fig. 1(b). On the right side of the figure, we show the extracted preimage for \(\mathbf{n} = (0, 0, -1)^T\) (white tube) and that for \(\mathbf{n} = (1, 0, 0)^T\) (black tube).

The torus shape of the \(m = -1\) component appears as a double-ring pattern in the cross-sectional plane at \(z = 0\), as shown in Fig. 1(c), where the density distributions of the \(m = \pm 1\) (left) and \(m = 0\) (right) components are shown in the gray scale. The distributions of \(m = \pm 1\) components overlap completely; therefore the system remains unmagnetized. This double-ring pattern can serve as an experimental signature of a knot and it should be probed by performing the Stern-Gerlach experiment on the BEC that is sliced at \(z = 0\).

Next, we show that knots can be created by manipulating an external magnetic field. In the presence of an external magnetic field, the time-dependent phase differences between different spin components are induced because of the linear Zeeman effect, which causes the Larmor precessions of \(\mathbf{n}\), while \(\mathbf{n}\) tends to become parallel to the magnetic field because of the quadratic Zeeman effect. Suppose that we prepare a BEC in the \(m = 0\) state, i.e., \(\mathbf{n} = (0, 0, 1)^T\), by applying a uniform magnetic field \(\mathbf{B}_0\) in the \(z\) direction. Then, we suddenly turn off \(\mathbf{B}_0\) and switch on a magnetic field given by \(\mathbf{B}(x) = b(r) \propto (\sin \theta \cos (\phi + \phi_0), \sin \theta \sin (\phi + \phi_0), \cos \theta)^T\), where \(b(r)\) is an arbitrary function and \(\phi_0\) is a real parameter. This magnetic field configuration is quadrupolar if \(\phi_0 = \pi\) and...
monopolar if $\phi_0 = 0$. In what follows, we shall consider the case of $\phi_0 = \pi$ and $b(r) = b'/r$, unless otherwise specified. Because of the linear Zeeman effect, $n$ starts rotating around the local magnetic field as $n = \exp[-i(\mu_B/2)\vec{B}(x) \cdot \vec{F}/h](0, 0, 1)^T$, and, therefore, the $n$ field winds as a function of $t$.

Figure 2 shows the dynamics of the creation and destruction of knots in a spherical trap subject to the quadrupole field. Figures 2(a)–2(d) show the snapshots of $\psi_{-1}$ (left) and preimages of $n = (0, 0, -1)^T$ and $n = (1, 0, 0)^T$ (right) at $t = 0.5T_L$, $1.1T_L$, $2.2T_L$, and $3.3T_L$, where $T_L = 2h/(\mu_B b' R_{TF})$ is the period of the Larmor precession at the Thomas-Fermi radius $R_{TF}$. The solid circle indicates the periphery of the BEC on the $xy$ plane. Knot-like objects enter the BEC from its periphery [Fig. 2(a)], and the number of knots increases as the $n$ field winds more and more with time [Fig. 2(b) and 2(c)]. With the passage of further time, however, the knot structure is destroyed, as shown in Fig. 2(d). The knots therefore have a finite lifetime, which will be discussed later. Figures 2(e)–2(h) show cross sections of the density for $m = -1$ (top) and $m = 0$ (bottom) components on the $xy$ plane at $t = 0.5T_L$, $1.1T_L$, $2.2T_L$, and $3.3T_L$. We find that as the $n$ field winds in time, the number of rings increases. This prediction can be tested by the Stern-Gerlach experiment. For $b' = 1$ G/cm and $R_{TF} = 30 \mu$m, we have $T_L = 0.5$ ms. Note that the axisymmetry of the system, which we assume in this Letter, is not essential for the creation of knots.

The knot soliton in the simple nonlinear $\sigma$ model without a higher derivative term is known to be energetically unstable, since the energy of the knot is proportional to its size $\xi_{knot}$, as can be seen by integrating the kinetic energy $\sim \xi_{knot}^{-2}$ over the volume of the soliton $\sim \xi_{knot}^3$. Knots will therefore shrink and finally disappear. In the case of an atomic gas BEC, however, the total energy of the system has to be conserved; therefore, the above-mentioned energetics argument does not imply the instability of knots in the present case.

The dominant decay mechanism for the knot in the spinor BEC is the spin current due to a spatial dependence of the $n$ field. The spin current induces local magnetization according to

$$\frac{\partial f_\mu}{\partial t} = -\nabla \cdot j^{\mu}_{\text{spin}} = \frac{\hbar}{M} \sum_{\nu, \lambda} \epsilon_{\nu \lambda \gamma} n_{\nu} \nabla^2 n_{\lambda}, \tag{4}$$

thereby destroying the polar state. The initial polar state will spontaneously develop into a biaxial nematic state, and eventually result in a fully polarized ferromagnetic domain. While $n$ is well defined in a biaxial nematic state as being parallel to one of the symmetry axes, it is ill defined in the fully magnetized region.

Substituting $n = e^{-i\alpha(r)\psi}F(0, 0, 1)^T$, which is used in Fig. 1, into Eq. (4), we can analytically calculate the time derivative of the local magnetization, whose maximum value is given by $\max_{x, t} |\frac{\alpha}{\psi}f(x, t = 0)| \approx 14.3h/(M\xi_{knot}^2)$. As the magnetization initially increases linearly as a function of time (see Fig. 3), we define the lifetime of a knot as $\tau_{knot} = [14.3h/(M\xi_{knot}^2)]^{-1}$. We also numerically calculate

FIG. 2 (color). Dynamics of the creation and destruction of knots in a spherical trap under a quadrupolar magnetic field. (a)–(d) The left sides of the figure show the isopycnic surface of $|\psi_{-1}|^2/\rho = 0.4$, and the color on the surface shows the phase of $\psi_{-1}$ at (a) $t = 0.5T_L$, (b) $1.1T_L$, (c) $2.2T_L$, and (d) $3.3T_L$, where $T_L = 2h/(\mu_B b' R_{TF})$. The white and black tubes on the right are the preimages of $n = (0, 0, -1)^T (n_x < -0.95)$ and $n = (1, 0, 0)^T (n_x > 0.95)$, respectively, and the solid circles represent the periphery of the BEC $|\rho/\rho(x = 0)| = 0.01$ in the $xy$ plane. (e)–(h) Cross sections of the density normalized by $\rho(x = 0)$ for $m = -1$ (top) and $m = 0$ (bottom) components in the $xy$ plane at (e) $t = 0.5T_L$, (f) $1.1T_L$, (g) $2.2T_L$, and (h) $3.3T_L$.

FIG. 3. Time evolution of the maximum of the local polarization in a spherical trap with $R_{TF} = 4.3\xi_{\text{knot}}$, starting from the knot shown in Fig. 1. The time is measured in units of $M\xi_{\text{knot}}^2/\hbar$. The dashed line shows $|f(x)|_{\text{max}} = t/\tau_{\text{knot}}$ (see text), which agrees well with the numerical result. The insets show $|f(x)|$ in the $xz$ plane, and the number below each panel shows the time elapsed in units of $M\xi_{\text{knot}}^2/\hbar$. The size of each panel is $1.9\xi_{\text{knot}} \times 3.8\xi_{\text{knot}}$.

the dynamics of the knot shown in Fig. 1 by solving the
time-dependent Gross-Pitaevskii equation; the result is shown in Fig. 3. In Fig. 3, we plot the maximum polarization as a function of time. The dashed line represents $|f(x)|_{\text{max}} = t/\tau_{\text{knot}}$ (see text), which agrees well with the numerical result for $t \ll \tau_{\text{knot}}$. The insets of Fig. 3 show the distribution of $|f(x)|$ on the $xz$ plane. The ferromagnetic domain emerges because of the spin current caused by the spatial dependence of $n$, and then it expands outward. In the case of a $^{23}\text{Na}$ BEC, the lifetime for a knot with $\xi_{\text{knot}} = 20$ $\mu$m is $\tau_{\text{knot}} = 10$ ms. The lifetime increases with increasing the size of knots.

Finally, we point out that knots in a BEC may be used as an experimental signature of a magnetic monopole. A magnetic monopole induces the magnetic field $B = h/(2\pi r^2)\hat{r}$, which acts in a manner similar to the quadrupole field and creates knots. Although $b(r)$ in this case diverges at $r = 0$, it forms a knotlike structure on a large scale. For instance, knots expand up to 10 $\mu$m in the period $43 \mu$s of Larmor precession at $r = 10$ $\mu$m, where $B = 33$ mG.

In conclusion, we have shown that a spin-1 polar Bose-Einstein condensate can accommodate a knot, which is also be shown to be created using a quadrupolar magnetic field. Contrary to knot solitons known in other systems, the knots in spinor BECs are immune from energetic instability against shrinkage, because the energy of the system is conserved; however they are vulnerable to destruction caused by spin currents because of the $n$ texture. The lifetime of a knot increases in proportion to the square of the size of knots and is shown to be sufficiently long to be observed in a Stern-Gerlach experiment.
